de Wind A, Geuskens GA, Ybema JF, Blatter BM, Burdorf A, Bongers PM, van der Beek AJ. Health, job characteristics, skills, and social and financial factors in relation to early retirement – results from a longitudinal study in the Netherlands. *Scand J Work Environment Health.* 2014;40(2):186–194. doi:10.5271/sjweh.3393

Objective This study aimed to investigate the relative contribution of health, job characteristics, skills and knowledge, and social and financial factors to the transition from work to (non-disability) early retirement.

Methods Employees aged 59–63 years (N=2317) were selected from the Study on Transitions in Employment, Ability and Motivation (STREAM) in the Netherlands. Individual characteristics, health, job characteristics, skills and knowledge, and social and financial factors were measured using a questionnaire at baseline. Information on early retirement was derived from the one-year follow-up questionnaire. Logistic regression analyses were used to identify predictors of early retirement. Population Attributable Fractions (PAF) were calculated.

Results Older age [odds ratio (OR) 1.79], poor physical health (OR 1.78), a positive attitude of the partner with respect to early retirement (OR 3.85), and the financial possibility to stop working before the age of 65 (OR 10.2) predicted the transition to early retirement, whereas employees that reported high appreciation at work (OR 0.58) and higher focus on development of skills and knowledge (OR 0.54) were less likely to retire early. PAF were 0.75 for the financial possibility to stop working, 0.43 for a positive attitude of the partner with respect to early retirement, 0.27 for low appreciation at work, 0.23 for a low focus on development, and 0.21 for poor health.

Conclusions The financial possibility to stop working before the age of 65 importantly contributes to early retirement. In the context of rapidly diminishing financial opportunities to retire early in the Netherlands, the prolongation of working life might be promoted by workplace health promotion and disability management, and work-related interventions focusing on appreciation and the learning environment.

Key terms ageing; employment; participation; predictor; relative contribution.

In the Netherlands and many other countries, the population is ageing. The ratio of retired elderly to the active working population is increasing, which causes pressure on the social security system. Moreover, a shortage of workers is expected in some sectors, eg, healthcare and the construction industry. To counter the pressure on the social security system and the expected worker shortage in the next decades, it is important that workers prolong their (healthy) working life until or beyond official retirement age. Although the average retirement age in the Netherlands increased from 61 years in 2003 to 63.1 years in 2011 (1), most workers still left work before the official retirement age of 65 in 2011.

In previous research, a variety of factors influencing (non-disability) early retirement have been identified. Van den Berg et al (2) and Schuring et al (3) reported that poor health predicts early retirement (odds, hazard, and risk ratios ranging from 1.2–3.4). High physical work demands (ie, extreme bending of the neck) predicted early retirement in one study [odds ratio (OR) 6.8], but no significant effect of high physical work demands has been found in other studies (OR ranging from 0.9–1.1) (2). High work pressure may also increase the likelihood of early retirement [hazard ratio (HR)1.1] (2). A qualitative study showed that organizational changes, including restructuring and continuous changes in the way work needed to

be done, and a poor social climate at work influenced the process towards early retirement as well (4). In addition to health and job characteristics, social factors may play a role in early retirement. Lund et al (5) found that having a partner increased the likelihood of early retirement (OR 2.8). A Dutch study found that support of the partner to continue working was associated with retirement at an older age (6). Besides this, skills and knowledge may influence early retirement. Provision of and participation in education and training was associated with a reduced intention to retire early and actual retirement behavior (7, 8). Moreover, colleagues' limited use of one's skills and knowledge may decrease motivation to work and result in early retirement according to qualitative research (4). In a longitudinal investigation, Fischer & Sousa-Posa (9) showed that pension systems offering more generous retirement options were associated with higher rates of early retirement. The previously mentioned qualitative study added that financial factors may shape a precondition to make the transition from work to early retirement among many employees (4). Hence, factors in the domains of health, job characteristics, knowledge and skills, and social and financial factors may push or pull workers from work to (non-disability) early retirement.

Although previous studies have provided insight into determinants of early retirement, these studies mostly focused on a limited set of determinants. Few studies address the importance of health and job characteristics relative to skills and knowledge, and social and financial factors. This is of interest because it provides insight into what interventions or regulations would (potentially) yield the greatest effect on the prolongation of working life. Moreover, the role of individual characteristics, such as mastery and life events, has barely been studied. Mastery refers to the degree to which persons feel that they are in control of matters that affect their lives (10) and has previously been associated with retirement adjustment (11). With respect to life events, qualitative research showed that employees who were confronted with the finiteness of life sometimes retired early to spend more time with family and friends, or spend more time on hobbies (12).

Therefore, the aim of the present study is to investigate the relative contribution of individual, health, and job characteristics, skills and knowledge, and social and financial factors to the transition from work to (non-disability) early retirement.

Methods

Study population

The study population consisted of participants of the Study on Transitions in Employment, Ability, and Moti-

vation (STREAM) (13). STREAM is a longitudinal study among 15 118 employees, self-employed persons, and persons without paid employment aged 45–64 years. The study population was stratified by age and employment status. STREAM consists of four yearly measurements in October and November of 2010, 2011, 2012, and 2013. In total 12 055 employees participated at baseline. In the present study, we used data from the first two waves of STREAM since data from the third and fourth wave were not available yet.

Inclusion criteria for the present study were: (i) employee at baseline and (ii) age 59–63 years. We chose 59 years as a lower age limit, since the proportion of employees that had retired early after one year strongly increased from this age onwards. We chose 63 years as the upper age limit at baseline because the official retirement age in The Netherlands was 65 years in these persons, and, hence, participants had not yet reached the official retirement age at one year follow-up.

Persons who received a disability pension or unemployment compensation at baseline or follow-up were excluded from the present study. Previous studies suggested that different factors and processes underlie the transition from work towards disability pension or unemployment (14).

Measurements

Participants completed an online questionnaire at baseline and at one-year follow-up. All independent variables were derived from the baseline questionnaire and the outcome variable "early retirement" was derived from the follow-up questionnaire.

Outcome

Information on early retirement was derived from a question on employment status. In this study, early retirement referred to employees who retired before the official retirement age of 65 years and did not receive disability compensation (ie, non-disability early retirement). This definition excluded persons who reported being both retired and working, and, hence, those who continued working after retirement (N=170).

Individual characteristics

Information on age, gender, and educational level was available. Educational level was measured using a question on the highest level of education completed with a diploma, and categorized into low (primary school, lower and intermediate secondary education, or lower vocational training), intermediate (higher secondary education, or intermediate vocational training) or high (higher vocational education or university).

Mastery was measured using the Pearlin Mastery Scale, which reflects the degree to which persons feel they are in control of matters that affect their lives (10), eg, "I have little control over things that happen to me". This scale consists of seven items with a 5-point answering scale ranging from "totally disagree" to "totally agree" (Cronbach's alpha 0.84).

Apart from that, the following life events in the past 12 months were assessed: got a serious illness, death of a partner, death of a close family member or friend, partner got a serious disease, and close family member or friend got a serious disease. In the analyses, we distinguished between persons who reported at least one of these life events and persons who did not.

Health

Perceived health was measured using the physical component summary scale (PCS) and the mental component summary scale (MCS) of the Short Form-12 Health Survey (15). The scales range from 0–100 (0=worst and 100=best possible health status). An example of an MCS item is: "Have you felt downhearted and blue?" An example of a PCS item: "Does your health now limit you in climbing several flights of stairs?" Due to the skewed distribution of both scales, the interquartile range (25th–75th percentile) was used to distinguish between poor, moderate, and good health.

Job characteristics

Physical load was measured using a scale consisting of six items on regular use of force, the use of vibrating tools, awkward postures, prolonged standing, and prolonged squatting based on the Netherlands Working Conditions Survey 2009 (16) and the Dutch Musculoskeletal Questionnaire (17) (Cronbach's alpha 0.86). A 5-point answer scale was used ranging from "always" to "(almost) never". Due to the skewed distribution, the interquartile range was used to distinguish between low, moderate, and high physical load.

Job demands and job autonomy were measured using four and five items, respectively, all derived from the Job Content Questionnaire (Cronbach's alpha 0.87 and 0.78, respectively) (18, 19). A 5-point scale was used ranging from "always" to "(almost) never". An example of a job demands is "Do you have to work very fast?". An example of an autonomy item is "Are you able to decide for yourself how to do your work?". Higher scores reflect higher job demands and higher job autonomy.

Restructuring was measured using one item, ie, "Has enterprise restructuring occurred in the past 12 months?" This item could be answered with "No", "Yes, without compulsory redundancies", and "Yes, with compulsory redundancies".

Furthermore, employees separately indicated on a 4-point scale whether appreciation and a good social climate were present at work (20). The answers "not present at all" and "somewhat present" were classified into "not present" and "rather present" and "highly present" were classified into "present".

In addition, social support of colleagues and the supervisor was measured using a 4-item scale derived from the COPSOQ (Cronbach's alpha 0.81) (21, 22). Employees indicated how often their colleagues or their supervisor helped or supported them and how often they were willing to listen to their work-related problems, eg, "How often do you get help and support from your immediate superior?". A 5-point answer scale was used ranging from "always" to "almost never". Lower scores reflect higher social support from colleagues and the supervisor.

Knowledge and skills

Developmental proactivity was measured using a 4-item scale derived from Van Veldhoven & Dorenbosch (23). This scale reflects the extent to which persons (i) actively search for activities in their job that allow them to expand knowledge and skills and (ii) adapt their knowledge and skills to (future) changes in their jobs, eg, "In my work, I search for people from whom I can learn something". Items could be answered on a 5-point scale ("totally disagree" to "totally agree") and Cronbach's alpha was 0.81. A higher score means a higher focus on development of skills and knowledge. The same 5-point answer scale was used to assess lack of knowledge by a single item, ie, "I lack 'new' knowledge and skills that have become important due to changes in my work". We categorized the answer options in three groups: no lack of knowledge, neutral, and lack of knowledge.

Social factors

Persons provided information on their household composition. If a person was married or living together with a partner, the respondent reported the support of this partner with respect to early retirement with one item based on Henkens et al (6), ie, "What would your partner think if you would stop working completely as soon as you get the opportunity?" The response categories were dichotomized into negative / neutral ("very upleasant", "unpleasant" and "not unpleasant, not pleasant") and positive ("pleasant" and "very pleasant").

Financial factors

The financial situation of the household was measured using the single question "What is the financial situation of your household now?". Employees could choose from the following answer categories: "very short of money",

"somewhat short of money", "just adequate", "some money left" or "a lot of money left". The categories were classified into "short of money", "just adequate", or "money left".

Furthermore, employees were asked: "Could you financially afford to stop working before the official retirement age?" This question could be answered with "yes", "no", or "don't know".

Statistical analysis

Descriptive statistics were used to describe the characteristics of the study population. To check whether loss to follow-up was selective, we compared baseline characteristics of non-responders and responders by means of independent T-tests.

Predictors of early retirement (no/yes) were studied by logistic regression analyses. Odds ratios (OR) and 95% confidence intervals (95% CI) were calculated to express the likelihood of the transition from work to early retirement. In the first step of the analyses, univariate associations between individual characteristics, health, job characteristics, knowledge and skills, social factors and financial factors with early retirement were established. Second, multivariate analyses were performed for all variables in the univariate analyses with P<0.20 within each of these domains. Third, multivariate analyses were performed for all variables from the previous step with P<0.20, using stepwise backward elimination. Variables with P<0.05 were retained in the final multivariate model. Age and gender were included in all analyses by default.

OR give information on the strength of the relation between a predictor and early retirement. Since the prevalence of this predictor is not taken into account, OR do not reflect the relative contribution of the predictor to the outcome on population level (24). To estimate the relative contribution of different predictors, population attributable fractions (PAF) were calculated for statistically significant predictors of early retirement in the final multivariate model (P<0.05; except for age). The following formula was used: PAF=Pe(OR-1)/(1+Pe(OR-1)), whereby Pe is the prevalence in the study population (25). This formula is meant for dichotomous variables. To calculate the PAF of categorical and continuous predictors in this study, these variables were dichotomized. Their prevalence was calculated and the final multivariate model was run again to obtain the OR to be included in the formula.

Statistical analyses were carried out using SPSS Statistics 20 (IBM Corp, Armonk, NY, USA).

Ethical issues

The Medical Ethical Committee of the VU University Medical Centre Amsterdam declared that the Medi-
cal Research Involving Human Subjects Act does not apply to STREAM. The Medical Ethical Committee had no objection to the execution of this study. In the information for participants that accompanied the online questionnaire, it was emphasized that the privacy of participants was guaranteed, all answers to the questions were treated confidentially, and all data were stored in secured computer systems.

Results

In total, 2317 persons were included (figure 1). At baseline, compared to participants, persons lost to follow-up reported (i) a slightly higher focus on development of skills and knowledge (3.87 versus 3.81), (ii) more often a worse household financial situation (short of money in 15% versus 13%, just adequate in 27% versus 23%, and money left in 59% versus 64%), and (iii) more often had no partner (30% versus 24%).

Table 1 shows the characteristics of the study population. In total 11.6% of the employees made the transition from work to early retirement (N=269). The correlation between baseline characteristics was small to moderate. Moderate associations were found between a good social atmosphere, the presence of appreciation, and social support of colleagues and the supervisor (Pearson's correlations ranging from 0.34–0.40). Also mastery and mental health were moderately interrelated (Pearson's correlation -0.35). Other variables were only marginally interrelated at baseline (Pearson's correlations ≤0.24).

In the univariate logistic regression analyses, older employees and those with a severe life event, poor physical health, a positive attitude of the partner with respect to early retirement, money left in the household and the financial possibility to stop working before the age of 65 years retired more often (table 2). Women and employees with higher job demands, appreciation at work, a good social work atmosphere, higher social support of colleagues and the supervisor, and a higher focus on development of skills and knowledge (ie, developmental proactivity) retired less often.

In the multivariate regression analyses, older age (OR 1.79), poor physical health (OR 1.78), a positive attitude of the partner with respect to early retirement (OR 3.85), not having a partner (OR 1.96) and having the financial possibility to stop working before the age of 65 (OR 10.2) predicted early retirement, whereas employees that reported high appreciation at work (OR 0.58) and higher focus on development (OR 0.54) retired less often. Life events, job demands, a good social atmosphere, social support of colleagues and the supervisor, and the financial situation of the household were not included in the final model (table 2). The influ-

ence of these factors was attenuated in the multivariate (domain) analyses.

Table 3 presents the PAF of the predictors included in the final multivariate regression model of early retirement. The relative contribution was highest for the financial possibility to stop working before the age of 65 (PAF 0.75), followed by a positive attitude of the partner with respect to early retirement (PAF 0.43), absence of appreciation at work (PAF 0.27), a low focus on development of skills and knowledge (PAF 0.23), and a poor physical health (PAF 0.21).

Discussion

Older age, poor physical health, a positive attitude of the partner with respect to early retirement and the financial possibility to stop working before the age of 65 predicted the transition from work to (non-disability) early retirement, whereas employees that reported high appreciation at work and higher focus on development of skills and knowledge retired less often. Especially the financial pos-

sibility to stop working before the age of 65, the attitude of the partner with respect to early retirement, and appreciation at work strongly contributed to early retirement.

Earlier studies have shown that poor health, work-related factors, skills and knowledge, and social and financial factors are determinants of early retirement

(2, 3, 5, 7–9). In the present study, the relation between financial factors and early retirement seems relatively strong compared to previous studies (26, 27). However, comparison to previous studies is hampered by differences in the aspects of the financial situation assessed and differences in the outcome variables. The relatively strong relationship between the financial possibility to stop working and early retirement compared to other predictors in the present study may (partly) be explained by the short follow-up period of one year. Since retirement is a process instead of a sudden event for many people, some employees may already have known it was financially possible to retire in the months before actual retirement, and hence, at the baseline assessment. It could be

hypothesized that the shorter the period of time between assessment of financial factors and early retirement, the stronger the association. This is supported by a previous qualitative study that showed that the financial possibility to retire early often becomes important after other push and pull factors towards retirement arise (4). Therefore, we recommend future research to study within one dataset whether the strength of the association between different predictors and early retirement depends on the period of time between the assessment of these variables.

Our finding on the influence of health on early retirement contradicts the results of a recent study, in which Robroek et al (28) found no significant effect of poor health on early retirement. These contradictory results might be explained by the fact that two distinct processes play a role. On the one hand, poor health could result in early retirement among persons who are not able to work at all, or experience a decrease in their ability to work. On the other hand, good health may contribute to early retirement among persons who want to enjoy life as long as their health allows them to do so (12).

As opposed to the review by Van den Berg et al (2), we did not find a significant relation between physical demands and task demands on the one hand, and early retirement on the other hand. This might (partly) be explained by the healthy worker effect. In the review by Van den Berg et al, much younger populations were included (≥25 years) than in our study (59–63 years). Our population may be a healthier population, since employees with health problems due to high physical and/or task demands may have dropped out of work before the age of 59. Another explanation might be that some employees who had retired at follow-up, had already planned to do so at baseline and had already reduced their physical and/or task demands.

Our result on the influence of partners supplements the finding that having a partner increases the likelihood of early retirement (5) and that partners' support to continue working positively influences retirement age (6). We obtained insight in the circumstances in which having a partner positively influences the transition from work towards early retirement. It is not so much having a partner that increases the likelihood of early retirement, but having a partner who stimulates such early retirement. Hence, our study endorses the importance of support of a partner in the retirement decision.

To our knowledge, the present study is the first study that investigated a wide range of predictors of early retirement at the same time, and hence, provided insight in the relative importance of different domains. Especially the financial possibility to retire early appeared to be important in the transition from work to early retirement. At the time of the data collection of the present study, early retirement schemes were still widely accessible, which may have contributed to the relatively large PAF for the

financial possibility to retire early in our study. Favorable arrangements to retire early will decline in the near future due to changes in the social security system with the official retirement age increasing from 65 in 2012 to 67 in 2023 in the Netherlands (29). This might affect the relative importance of predictors of early retirement addressed in the present study. Moreover, the decline in favorable early retirement schemes might decrease the proportion of persons who leave the workforce through early retirement, but might increase the proportion of persons who leave the workforce via different pathways, eg, disability pensions or unemployment. We would recommend future research to investigate changes in the relative importance of predictors of early retirement and pathways out of employment.

A strength of the present study is that we used longitudinal data, which allowed us to investigate predictors of early retirement instead of associations between early retirement and certain characteristics. Moreover, we studied a broad set of predictors in a diversity of domains and participants performed a broad variety of jobs. However, this study also has limitations. A first limitation is the previously mentioned short follow-up period of one year, which may have influenced baseline measurements and their associations with early retirement. For example, employees who knew they would retire during the next months possibly focused less on the development of new skills, had already reduced their physical and job demands, and knew it was financially possible to stop working. Second, the response of the study was 83%. Although this response is high and differences between respondents and non-respondents were small, bias due to non-response at follow-up cannot be ruled out. Third, due to the large number of predictors we investigated in the present study, there is a risk of overlap between the predictors of interest. To minimize this risk, we performed multivariate domain analyses, and thereby reduced the number of predictors in the final multivariate model. Fourth, in line with Van den Berg et al (14) and Mykletun et al (30), we used OR instead of relative risks to calculate PAF. This may have resulted in some overestimation of the PAF. However, since the sum of the PAF exceeds 1, we would like to point out that the presented PAF should be interpreted only as a measure of ranking the relative importance of different factors rather than an exact estimate of the proportion of workers with early retirement due to a specific predictor. Fifth, all data relied on self-reports since register data were not available. It may be difficult to measure certain job characteristics, such as physical demands (31), by self-report, but previous research showed that subjective health assessments are valid health status indicators in middle-aged populations (32). To our knowledge, no previous study investigated the validity of self-reported employment status. However, for none of the variables

we have reasons to assume differential misclassification. Sixth, the item measuring the financial possibility to stop working explicitly referred to "retirement", in contrast to other independent variables. This may have contributed to the relatively strong relation with early retirement in addition to the short follow-up period. Seventh, differences between subgroups of employees were not presented due to a lack of statistical power. Additional analyses stratified by gender and educational level did not reveal substantial differences. However, the relation between a positive attitude of the partner with respect to stopping to work and early retirement might be stronger among high- compared to low-educated employees. We recommend future studies with sufficient statistical power to investigate differences between subgroups of workers. Finally, data collection took place at the same time as an extensive public debate on the need to prolong working life in the Netherlands. Employees might have felt obligated to continue working, which might have buffered the relation between the predictors that were studied and early retirement.

In conclusion, our results indicated that especially the financial possibility to stop working before 65 played an important role in the transition from work towards early retirement. On the basis of these results, we expect that the present gradual increase of the official retirement age and constraining the financial possibilities to retire early will indeed contribute to the prolongation of working life. In the context of rapidly diminishing financial opportunities to retire early in the Netherlands, the prolongation of working life may be supported by health-promotion programs in the workplace. Moreover, since more older workers are expected to continue working in spite of chronic health problems in the future, disability management may also gain importance to support extended working careers. Previous reviews have shown that these interventions may positively affect health and work-related outcomes, including absenteeism, presenteeism, and work performance (33, 34). Furthermore, the prolongation of working life might be supported by work-related interventions, focusing on appreciation and the learning environment. Jobs could for example be designed in such a way that persons are continuously stimulated to expand their knowledge and skills and adapt their knowledge and skills to changes in their work. The results of the present study show that the causes of early retirement are multifactorial, which advocates that policies, regulations, and interventions focus on a diversity of factors to prolong working lives.
